Isotope effects in reactions between \( \text{Mg}^+ \) in the \( 3p^2 P_{3/2} \) excited state and molecular hydrogen at thermal energies are studied through single reaction events. From only \( \sim 250 \) reactions with HD, the branching ratio between formation of \( \text{MgD}^+ \) and \( \text{MgH}^+ \) is found to be larger than 5. From an additional 65 reactions with \( \text{H}_2 \) and \( \text{D}_2 \) we find that the overall fragmentation probability of the intermediate \( \text{MgH}_2 \), \( \text{MgHD}^+ \), or \( \text{MgD}^+_2 \) complexes is the same. Our study shows that few single ion reactions can provide quantitative information on ion-neutral reactions. Hence, the method is well suited for reaction studies involving rare species, e.g., rare isotopes or short-lived unstable elements.

Isotope effects often play an important role for the outcome of chemical reactions. For instance, the chemical composition of interstellar clouds is strongly influenced by isotope effects in certain reactions [1]. In laboratory experiments, isotope effects observed in isotopic analogs of chemical reactions can provide details about the reaction dynamics. Substitution reactions of the type \( \text{F} + \text{HD} \) and \( \text{Cl} + \text{HD} \) are among the simplest reactions where isotope effects can be present. They were already studied when the first chemical lasers were developed, in order to understand the population inversion mechanism and to identify the laser transitions [2]. These studies together with studies of the \( \text{F} + \text{D}_2 \) reaction strongly stimulated the whole field of reactive scattering [3]. Especially the resonance effects observed in the \( \text{F} + \text{H}_2 \) reaction and isotopic analogs [4] have been subject to numerous experimental and theoretical studies finally resulting in a much improved understanding of this benchmark reaction [3,5]. In another series of experiments, reactions between a beam of ground state atomic ions and \( \text{H}_2 \), HD and \( \text{D}_2 \) have been studied. Strong isotope effects have been observed and, e.g., in reactions between alkaline earth ions (\( \text{X}^+ \)) and HD, it was found that XD\(^+\) formation is preferred for some alkaline earth ions, while XH\(^+\) formation is preferred for others [6,7].

Within the last few years, new techniques have emerged for ion-neutral reaction studies, e.g., of cold reactive collisions [8], single ion reactions [9] as well as reaction dynamics by applying crossed molecular beam imaging [10]. These techniques open up new possibilities in the field of ion-neutral reactive scattering.

In this Letter, we investigate isotope effects in reactions of single ions with the isotopologues of molecular hydrogen, a model system for ion-neutral reactions. More specifically, we consider reactions at thermal energies with \( \text{Mg}^+ \) in the \( 3p^2 P_{3/2} \) excited state (excitation energy of 4.4 eV). Because of the simple internal structure of the reaction partners, the studied reactions represent a simple test case for reaction dynamics involving an electronically excited atomic collision partner. We make use of an experimental technique with almost 100% efficiency in detecting single reaction events [9]. With a total of only about 300 reactions, the branching ratio between the reactions

\[
\text{Mg}^+ (3p^2 P_{3/2}) + \text{HD} \rightarrow \text{MgD}^+ + \text{H}
\]

\[
\rightarrow \text{MgH}^+ + \text{D}
\]

has been found to be larger than 5. In reactions with \( \text{H}_2 \), HD and \( \text{D}_2 \) the reaction paths leading to either \( \text{MgH}^+ \) or \( \text{MgD}^+ \) formation from a \( \text{MgH}_2 \), \( \text{MgHD}^+ \) or \( \text{MgD}^+_2 \) complex have been found to be equally likely within statistical uncertainties. Our experiments demonstrate the prospects for similar single molecular ion studies using, e.g., state prepared molecular ions [11], more complex molecular ions [12,13], or molecular ions of astrophysical relevance [14,15]. The high detection efficiency can furthermore be useful for studies of reactions involving ions of rare species, e.g., superheavy elements [16].

In our study we use a linear Paul trap setup which is described in detail in Ref. [17]. Briefly, as shown in Fig. 1, the trap consists of four cylindrical rods, each sectioned into three parts. By applying suitable ac and dc voltages (not indicated in Fig. 1) a harmonic confining potential is created with oscillation frequencies \( \omega_x = \omega_y > \omega_z \) along the \( x \), \( y \) and \( z \) axes, respectively. \( ^{26}\text{Mg}^+ \) ions are loaded into the trap by crossing an effusive beam of \( \text{Mg} \) atoms with a laser beam at 285 nm in the trap center for resonance-enhanced isotope selective two-photon ionization of \( ^{26}\text{Mg} \) [18,19]. The \( ^{26}\text{Mg}^+ \) ions are Doppler laser cooled on the \( 3s^2S_{1/2} - 3p^2 P_{3/2} \) transition near 280 nm (total intensity \( \sim 1 \) W/cm\(^2\)). Individual ions are observed by imaging light, emitted spontaneously during the laser cooling process, onto a charge-coupled device (CCD) camera.

Reactions with HD, \( \text{H}_2 \) or \( \text{D}_2 \) molecules are investigated by first leaking the gasses into the trap chamber until a steady-state pressure of about \( 10^{-9} \) Torr is reached, and then loading two \( ^{26}\text{Mg}^+ \) ions into the trap. Reactions exclusively take place with \( ^{26}\text{Mg}^+ \) ions excited to the...
The Coulomb interaction with the remaining laser cooled molecular ion is formed, it is sympathetically cooled through case, but 10 eV trap depth could easily be employed if a small fraction of the trap depth (\(10^{-24}\)) [20]. After a reaction, the formed molecular ion stays excited hydrogen molecules are not energetically allowed (c.m.) mode of the cold two-ion system along the z axis. Since the c.m. mode oscillation period (typically \(10 \mu s\)) depends on the masses of both ions, the mass of the reaction product ion can now be determined [9].

For unambiguous identification of the molecular ion species, its mass is determined by applying the identification technique demonstrated for CaO+ ions in Ref. [9]. In short, the method relies on exciting the center-of-mass (c.m.) mode of the cold two-ion system along the z axis by applying a voltage oscillating at a frequency \(\nu_{\text{mod}}\) to two of the end-electrodes as shown in Fig. 1. When \(\nu_{\text{mod}}\) is equal to the eigenfrequency of the c.m. mode, the motion of the ions is resonantly excited. This excitation is clearly visible in the CCD-images as a smearing out of the fluorescence light from the \(^{26}\text{Mg}^+\) ion along the z axis (see Fig. 2) due to the long exposure time (100 ms) compared to the c.m. mode oscillation period (typically \(\sim 10 \mu s\)). Since the c.m. eigenfrequency depends on the masses of both ions, the mass of the reaction product ion can now be determined [9].

In practice, the modulation frequency is scanned in five steps through a 100 Hz narrow frequency interval around \(\nu_{\text{m}}\), where \(\nu_{\text{m}}\) denotes the c.m. mode eigenfrequency for one \(^{26}\text{Mg}^+\) ion and one singly-charged ion of mass \(m\), and at each step a CCD image is recorded. Such images are shown in Fig. 2 for one \(^{26}\text{Mg}^+\) ion trapped simultaneously with another \(^{26}\text{Mg}^+\) ion, a \(^{26}\text{MgH}^+\) ion and a \(^{26}\text{MgD}^+\) ion while modulation frequencies of \(\nu_{26}, \nu_{27}\) and \(\nu_{28}\) are applied successively. In the experiments, modulation frequencies \(\nu_{28}, \nu_{27}, \nu_{26}, \nu_{25}\) and \(\nu_{24}\) are applied repeatedly until one \(^{26}\text{Mg}^+\) ion has reacted and the reaction product has been identified. This product ion was \(^{26}\text{MgD}^+\) or \(^{26}\text{MgH}^+\) in all but two cases where a \(^{24}\text{Mg}^+\) ion produced in a charge exchange collision was observed (as in Ref. [19] for calcium). The choice of working with the less abundant \(^{26}\text{Mg}^+\) ion instead of the dominant \(^{24}\text{Mg}\) isotope (80% natural abundance) was made to avoid problems in distinguishing \(^{24}\text{MgH}^+\) and \(^{24}\text{MgD}^+\) ions from \(^{25}\text{Mg}^+\) and \(^{26}\text{Mg}^+\) ions, respectively, formed in charge exchange collisions with background gas Mg atoms [19]. At the applied molecular gas pressure (\(\sim 10^{-9}\) Torr), the \(\text{Mg}^+ - \text{H}_2/\text{HD}/\text{D}_2\) reaction rate is less than one per minute, which means that the above identification procedure can in general be applied before both of the initially loaded atomic ions have reacted. After a reaction product has been identified the trap is emptied, two new \(^{26}\text{Mg}^+\) ions are loaded and the experiment repeated.

In our study of the branching ratio between reactions (1) and (2), the unavoidable background pressure of \(\text{H}_2\) needs to be accounted for. This is done by measuring the number of \(^{26}\text{MgD}^+\) ions, \(N_{\text{MgD}}\), and \(^{26}\text{MgH}^+\) ions, \(N_{\text{MgH}}\), formed at four different ratios of the partial pressure of HD and \(\text{H}_2\), \(P_{\text{HD}}/P_{\text{H}_2}\). The obtained results are presented in Fig. 3 and show an increase of \(\text{MgD}^+\) formation with increased HD pressure.

To understand quantitatively the branching ratio between reactions (1) and (2), we model the reactions as two-step processes. In the first step the neutral molecule is assumed to be captured by the \(^{26}\text{Mg}^+\) ion at long range to form a \(\text{MgH}_2^+\) or \(\text{MgHD}^+\) collision complex and, in the second step, a stable \(\text{MgH}^+\) or \(\text{MgD}^+\) ion is formed from this complex at short range. The capture cross-section for the first step is for the present collision energies well approximated by the Langevin capture cross section \(\sigma = (\epsilon/2\epsilon_0)\sqrt{\alpha/(\mu v^2)}\) [21], where \(\alpha\) is the polarizability of the neutral molecule, \(\mu\) is the reduced mass, and \(v\) is the relative velocity in the center-of-mass system. Since the polarizability of \(\text{H}_2\) and HD is equal within 1% [22], in our
much larger than the extension of the hydrogen molecule.

\[
N/M = 0.0017 M
\]

where \(s\) is determined with a restgas analyzer and for all values of the ratio of the MgH\(^+\) ion formation rate \(N/M\) is the efficiency of \(M\)\(^+\) (MgH\(^+\) or MgD\(^+\)) formation after reaction with \(M\) (H\(_2\) or HD). This expression approaches the branching ratio \(\eta_{\text{MgD}}/\eta_{\text{MgH}}\) for large values of \(P_{\text{HD}}/P_{\text{H}_2}\), i.e., when the vast majority of MgH\(^+\) molecules are produced from reactions with HD rather than H\(_2\). The expression is independent of \(P_{\text{exc}}\) and of the absolute partial pressures, which greatly reduces systematic errors. The relative partial pressures are measured with a restgas analyzer and for all values of the ratio \(P_{\text{HD}}/P_{\text{H}_2}\) we estimate its systematic uncertainty to be less than 25\%. From the parameters determined from the fit (see Fig. 3), the branching ratio \(\eta_{\text{MgD}}/\eta_{\text{MgH}}\) can be determined. Taking the statistical uncertainties into account, we find that the branching ratio is unbound from above and has a lower limit of 5, thus demonstrating a dramatic intramolecular isotope effect. In addition, the ratio \(\eta_{\text{MgH}}/\eta_{\text{MgH}^+}\) is consistent with unity which indicates that the probability of forming a magnesium hydride ion is equally large from any of the two complexes MgH\(_2^+\) or MgHD\(^+\).

In a second series of measurements we studied reactions between Mg\(^+\) and a mixture of 43\% H\(_2\) and 57\% D\(_2\) gas. We observed the production of 40 MgH\(^+\) ions and 25 MgD\(^+\) ions which yields a ratio of 2.1 \pm 0.6 between the MgH\(^+\) and MgD\(^+\) reaction rate coefficients. Using the same two-step model as above it follows that \(\eta_{\text{MgH}}/\eta_{\text{MgD}} = 1.5 \pm 0.4\).

Substitution reactions between a \(\text{MgH}^+\) or \(\text{MgD}^+\) ion and a H\(_2\), HD or D\(_2\) molecule could potentially give rise to a systematic error. Such reactions were, however, only observed on two occasions (one MgH\(^+\) + D\(_2\) \rightarrow MgD\(^+\) + HD, one MgD\(^+\) + H\(_2\) \rightarrow MgH\(^+\) + HD) in a period of more than 20 min and hence they do not give rise to systematic errors on the results presented here.

The most striking of the above results is the strong intramolecular isotope effect in reactions (1) and (2). This finding cannot be explained by a simple statistical model based on an assumption of an equal probability for populating energetically accessible states of \(\text{MgH}^+\) and \(\text{MgD}^+\). This assumption only gives rise to \(\eta_{\text{MgD}}/\eta_{\text{MgH}} \approx 2\) and therefore we attribute the observed isotope effect to a dynamical mechanism. In the ion beam experiments of Ref. [6] a similar isotope effect has been observed in reactions between ground state Mg\(^+\) ions and HD molecules at center-of-mass energies up to 11 eV. This was rationalized in terms of an impulsive interaction with a thermodynamic threshold.

A schematic view of the potential surfaces involved in the reaction is shown in Fig. 4. The analogous potential surfaces for MgD\(_2^+\) was explored in a photofragmentation study where MgD\(^+\) formation was observed after laser excitation from the \(1^2A_1\) state to the red of the Mg\(^+\) (3\(p\)) + D\(_2\) asymptote [23]. From the observed MgD\(^+\) spectrum it was argued that MgD\(^+\) is formed by direct and fast reactions on the \(1^2B_2\) surface in \(C_{2v}\) geometry through a bond-stretch mechanism as well as from the \(1^2B_1\) state, possibly through a coupling to the \(1^2B_2\) state. On the \(1^2B_2\) potential surface the Mg\(^+\) ion becomes inserted in the D\(_2\) bond such that the D-D bond is stretched and eventually broken and a Mg\(^+\)-D bond is formed [23,24]. In addition, in this study no dissociation into Mg\(^+\) (3\(p\)) + D\(_2\) was observed. In our two-step model this corresponds to the values of \(\eta_{\text{MgH}^+}\), \(\eta_{\text{MgD}^+}\), and \(\eta_{\text{MgH}^+} + \eta_{\text{MgH}^+}\) being close to unity, which
The investigation of photofragmentation indicate that the Mg\(^+\) + HD reaction discussed in the present paper proceeds via the 2\(^2\)A' potential surface through a bond-stretch mechanism that eventually favors the formation of MgD\(^+\) [23,24]. To fully understand the transition from a MgHD\(^+\) complex to a potential surface favoring the MgD\(^+\) + H asymptote rather than the MgH\(^+\) + D asymptote requires a detailed theoretical study. It might be necessary to consider the details of the conical intersection which arises from the crossing of the 1\(^2\)A' and 2\(^2\)A' potential surfaces. Nonadiabatic couplings at the conical intersection could give rise to a preference of the MgD\(^+\) channel over the MgH\(^+\) channel. Our results suggest that the observed isotope effect arise through a dynamic mechanism in the exit channel of the reaction. The same mechanism could be responsible for the isotope effect observed in reactions with ground state Mg\(^+\) ions in Ref. [6] where it was suggested that thermodynamic threshold effects in the entrance channel could lead to a preference of MgD\(^+\) production. The distribution over rovibrational levels in the formed molecular ion has not been investigated in the present study. It may contribute further information on dynamical effects in the exit channel, as found in studies of the analogous reactions between excited state neutral Mg [26] as well as Na [27] and HD.

In conclusion, we have found that reactions between Mg\(^+\) in the 3\(p\) \(^2\)P\(_{3/2}\) excited state and HD molecules at thermal energies preferentially leads to the formation of MgD\(^+\) rather than MgH\(^+\) with a branching ratio larger than 5. Additional reactions with H\(_2\) and D\(_2\) have shown that after a reaction complex has formed, expectedly through a Langevin capture process, the molecular ion formation efficiencies after capture of a HD, H\(_2\), or D\(_2\) molecule are equal within statistical uncertainties. The efficiencies are consistent with unity which is in agreement with observations in a previous study of MgD\(^+\) photofragmentation [23]. Our measurements demonstrate that it is possible to determine quantitatively the branching ratios and relative reaction rates in ion-neutral reactions by observing only a few hundred single reactions. The method should in the future be applicable to a variety of studies, e.g., of astrophysically relevant reactions, chemistry of superheavy elements and reactions involving more complex molecules.
